(Dated: February 6, 2020)

Green algae of the *Volvocine* lineage, spanning from unicellular *Chlamydomonas* to vastly larger *Volvox*, are models for the study of the evolution of multicellularity, flagellar dynamics, and developmental processes. Phototactic steering in these organisms occurs without a central nervous system, driven solely by the response of individual cells. All such algae spin about a body-fixed axis as they swim; directional photosensors on each cell thus receive periodic signals when that axis is not aligned with the light. The flagella of *Chlamydomonas* and *Volvox* both exhibit an adaptive response to such signals in a manner that allows for accurate phototaxis, but in the former the two flagella have distinct responses, while the thousands of flagella on the surface of spherical *Volvox* colonies have essentially identical behaviour. The planar 16-cell species *Gonium pectorale* thus presents a conundrum, for its central 4 cells have a *Chlamydomonas*-like beat that provide propulsion normal to the plane, while its 12 peripheral cells generate rotation around the normal through a *Volvox*-like beat. Here, we combine experiment, theory, and computations to reveal how *Gonium*, perhaps the simplest differentiated colonial organism, achieves phototaxis. High-resolution cell tracking, particle image velocimetry of flagellar driven flows, and high-speed imaging of flagella on micropipette-held colonies show how, in the context of a recently introduced model for *Chlamydomonas* phototaxis, an adaptive response of the peripheral cells alone leads to photo-reorientation of the entire colony. The analysis also highlights the importance of local variations in flagellar beat dynamics within a given colony, which can lead to enhanced reorientation dynamics.

I. INTRODUCTION

Since the work of A. Weismann on germ-plasm theory in biology [1] and of J.S. Huxley on the nature of the individual in evolutionary theory [2], the various species of green algae belonging to the family *Volvocaceae* have been recognized as important ones in the study of evolutionary transitions from uni- to multicellular life. In a modern biological view [3], this significance arises from a number of specific features of these algae, including the fact that they are an extant family (obviating the need to study fossils), are readily obtainable in nature, have been studied from a variety of perspectives (biochemical, developmental, genetic), and have had significant ecological studies. From a fluid dynamical perspective [4], their relatively large size and easy culturing conditions allow for precise studies of their motility, the flows they create with their flagella, and interactions between organisms, while their high degree of symmetry simplifies theoretical descriptions of those same phenomena [5].

As they are photosynthetic, the ability of these algae to execute phototaxis is central to their life. Because the lineage spans from unicellular to large colonial forms, it can be used to study the evolution of multicellular coordination of motility. Motility and phototaxis of motile green algae have been the subjects of an extensive literature

in recent years [6–13], focusing primarily on the two extreme cases: unicellular *Chlamydomonas* and much larger *Volvox*, with species composed of 1,000 – 50,000 cells. *Chlamydomonas*, the simplest member of the *Volvocine* family, swims typically by actuation of its two flagella in a breast stroke, combining propulsion and slow body rotation. It possesses an *eye spot*, a small area highly sensitive to light [14, 15], which triggers the two flagella differently [16]. Those responses are adaptive, on a timescale matched to the rotational period of the cell body [17–19], and allow cells to scan the environment and swim towards light [13]. Multicellular *Volvox* shows a higher level of complexity, with differentiation between interior germ cells and somatic cells dedicated to propulsion. Despite lacking a central nervous system to coordinate its cells, *Volvox* exhibits accurate phototaxis. This is also achieved by an adaptive response to changing light levels, with a response time tuned to the *colony* rotation period which creates a differential response between the light and dark sides of the spheroid [7, 20].

In light of the above, a natural question is: how does the simplest *differentiated* organism achieve phototaxis? In the *Volvocine* lineage the species of interest is *Gonium*. This 8- or 16-cell colony represents one of the first steps to true multicellularity [22], presumed to have evolved from the unicellular common ancestor earlier than other *Volvocine* algae [23]. It is also the first to show cell differentiation. We focus here on 16-cell colonies, which show a higher degree of symmetry than those with 8, but our results apply to both.

FIG. 1. Geometry and locomotion of *Gonium pectorale*. (a) 16-cell colony. Each cell has two flagella, 30 – 40 μm long. Scale bar is 10 μm . (b) Schematic of a colony of radius a : 16 cells (green) each with one eye spot (orange dot). The *cis* flagellum is closest to the eye-spot, the *trans* flagellum is furthest [21]. Flagella of the central cells beat in an opposing breaststroke, while the peripheral flagella beat in parallel. The pinwheel organization of the peripheral flagella leads to a left-handed body rotation at a rate ω_3 . (c) Upward swimming of a colony. Superimposition of images separated by 0.4 s. Green spots label one specific cell to highlight the left-handed rotation. Scale bar is 20 μm . (d) Sketch of a helical trajectory: a colony (green ellipsoid) swims with velocity \mathbf{U} along an oscillatory path (blue line) of wavelength λ , amplitude A and pitch angle χ . The frame $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$ is attached to the *Gonium* body.

A 16-cell *Gonium* colony is shown in Fig. 1. It is organized into two concentric squares of respectively 4 and 12 cells, each biflagellated, held together by an extracellular matrix [24]. All flagella point out on the same side: it exhibits a much lower symmetry than *Volvox*, lacking anterior-posterior symmetry. Yet it performs similar functions to its unicellular and large colonies counterparts as it mixes propulsion and body rotation, and swims efficiently towards light [6, 25, 26]. The flagellar organization of inner and peripheral cells deeply differs [27, 28]: central cells are similar to *Chlamydomonas*, with the two flagella beating in an opposing breast stroke, and contribute mostly to the forward propulsion of the colony. Cells at the periphery, however, have flagella beating in parallel, in a fashion close to *Volvox* cells [21]. This minimizes steric interactions and avoids flagella crossing each other [6]. Moreover, these flagella are implanted with a slight angle and organized in a pin-wheel fashion (see

Fig. 1b) [27]: their beating induces a left-handed rotation of the colony, highlighted in Figs. 1c&d and in Supplementary Movie 1. Therefore, the flagella structure of *Gonium* reinforces its key position as intermediate in the evolution towards multicellularity and cell differentiation.

These small flat assemblies show intriguing swimming along helical trajectories - with their body plane almost normal to the swimming direction - that have attracted the attention of naturalists since the eighteenth century [25, 26, 29]. Yet, the way in which *Gonium* colonies bias their swimming towards the light remains unclear. Early microscopic observations have identified differential flagellar activity between the illuminated and the shaded sides of the colony as the source of phototactic reorientation [25, 26]. Yet, a full fluid-dynamics description, quantitatively linking the flagellar response to light variations and the hydrodynamic forces and torques acting on the colony, is still lacking. From an evolutionary perspective, phototaxis in *Gonium* also raises a number of fundamental issues: to what extent is the phototactic strategy of the unicellular ancestor retained in the colonial form? How is the phototactic flagella reaction adapted to the geometry and symmetry of the colony, and how does it lead to an effective reorientation?

Taking this specific structure into account, here we aim to understand how the individual cell reaction to light leads to reorientation of the whole colony. Any description of phototaxis must build on an understanding of unbiased swimming, so we first focus on the helical swimming of *Gonium*, and show how it results from an uneven distribution of forces around the colony. We then investigate experimentally its phototaxis, by describing the reorientation trajectories and characterising the cells' response to light. That response is shown to be adaptive, and we therefore extend a previously introduced model for such a response to the geometry of *Gonium*, and show how the characteristic relaxation times are finely tuned to the *Gonium* body shape and rotation rate to perform efficient phototaxis.

II. FREE SWIMMING OF GONIUM

A. Experimental observations

We recorded trajectories of *Gonium* colonies freely swimming in a sealed chamber on an inverted microscope, connected to a high speed video camera, as sketched in Fig. 2a and detailed in Appendix A. To obtain unbiased random swimming trajectories, we used red light illumination. Trajectories were reconstructed using a standard tracking algorithm [30], and shown in Fig. 3a and Supplementary Movie 2. They exhibit a large variation in waviness, with some colonies swimming along nearly straight lines, while others show highly curved helices. From Fig. 1c-d, we infer that a colony performs a full body rotation per helix wavelength. This observation suggests that the waviness of the trajectories arises from an uneven dis-

FIG. 2. Phototaxis experiments. (a) *Gonium* colonies swim in a sealed chamber made of two glass slides, with non-phototactic red illumination from above, on the stage of an inverted microscope connected to a high speed video camera. Two blue LEDs on the right- and left-hand sides of the chamber can independently shine light with controllable intensities. (b) Micropipette experiments. A micropipette of inner diameter $\sim 20 \mu\text{m}$ holds a colony (green disc) in a chamber made of two glass slides, spaced to allow room for optical fiber connected to a blue LED to enter the chamber.

tribution of forces developed by the peripheral flagella, with the most active flagella located on the outer side of the helix.

From image analysis, we extracted for each colony the body radius a , the body rotation frequency $\nu_3 = \omega_3/2\pi$, the instantaneous swimming velocity v projected in the plane of observation, and the mean swimming velocity v_m . The rotation frequency $\nu_3 \sim 0.4$ Hz, decreases slightly with colony size as shown in Fig. 3b. This places *Gonium* in a consistent intermediate position between *Chlamydomonas* and *Volvox*, whose radii are respectively about $5 \mu\text{m}$ and $200 \mu\text{m}$, and whose rotation rates are 2 Hz and 0.2 Hz [7, 31]. With a typical flagellar beating frequency of 10 Hz (see measurements in Sec. III), there are ~ 25 flagella strokes per body rotation, a value similar to that in *Chlamydomonas*.

There is a significant correlation between the swimming velocity and the waviness of the trajectories, displayed in Fig. 3c. We quantify the degree of waviness with the pitch angle χ , defined as the angle between the swimming speed \mathbf{U} and the helix axis $\hat{\mathbf{e}}_z$, such that $\tan \chi = (2\pi A/\lambda)$, with A and λ the helix amplitude and wavelength (see Fig. 1d). Swimming in helices is clearly at the cost of the swimming efficiency: the ratio v_m/v shows a marked decrease with the angle χ . The data is well described by the simple law $v_m/v = \cos \chi$ expected for a helix traced out at constant instantaneous velocity (black line in Fig. 3c). This geometrical law is valid for a 3-dimensional velocity v_{3D} , while we only have access to its two-dimensional projection. In Appendix B we show

that v (the projected velocity) provides a reasonable approximation to the real velocity v_{3D} for χ not too large. The average pitch angle in Fig. 3c is $\chi \simeq 30^\circ \pm 13^\circ$, corresponding to a mean velocity experimentally 30% slower than the instantaneous velocity. In spite of this decreased swimming efficiency, the surprisingly high level of waviness found in most *Gonium* colonies suggest that this trait provides an evolutionary advantage.

B. Fluid dynamics of the swimming of *Gonium*

We introduce here the fluid dynamical and computational description of the swimming of *Gonium*. With a typical size of $40 \mu\text{m}$ and swimming speed of $40 \mu\text{m/s}$, the Reynolds number is of order 10^{-3} , so the swimming is governed by the Stokes equation, *i.e.* by the balance between the force and torque induced by the flagella motion to those arising from viscous drag [32].

We model a colony as a thick disk of symmetry axis $\hat{\mathbf{e}}_3$. This disk includes the averaged cell body radius a , and also the flagella, which contribute significantly to the total friction. We therefore consider an effective radius R encompassing the whole structure. In the frame $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3)$ attached to the body, the viscous force \mathbf{F}_v and torque \mathbf{L}_v are linearly related to the velocity \mathbf{U} and angular velocity $\boldsymbol{\Omega}$ through

$$\mathbf{F}_v = -\eta R \begin{bmatrix} k_1 & 0 & 0 \\ 0 & k_1 & 0 \\ 0 & 0 & k_3 \end{bmatrix} \mathbf{U}, \quad (1a)$$

$$\mathbf{L}_v = -\eta R^3 \begin{bmatrix} l_1 & 0 & 0 \\ 0 & l_1 & 0 \\ 0 & 0 & l_3 \end{bmatrix} \boldsymbol{\Omega}, \quad (1b)$$

where $\eta = 1 \text{ mPa s}$ is the viscosity of water, and the numbers (k_1, k_3, l_1, l_3) quantifying the translation and rotation friction along the transverse and axial directions respectively, characteristic of the *Gonium* geometry. Left-handed body rotation implies $\mathbf{U} \cdot \boldsymbol{\Omega} < 0$. The angular velocity $\boldsymbol{\Omega}$ is expressed in the body frame by introducing the Euler angles (θ, ϕ, ψ) defined in Fig. 4a [33],

$$\boldsymbol{\Omega} = \begin{bmatrix} \dot{\theta} \cos \psi + \dot{\phi} \sin \theta \sin \psi \\ -\dot{\theta} \sin \psi + \dot{\phi} \sin \theta \cos \psi \\ \dot{\psi} + \dot{\phi} \cos \theta \end{bmatrix}. \quad (2)$$

These viscous forces and torques are balanced by the thrust and spin induced by the action of the flagella. The central flagella produce a net thrust $F_c \hat{\mathbf{e}}_3$ and no torque. The peripheral flagella contribute both to propulsion and rotation: we model them in the continuum limit as an angular density of force in the form $d\mathbf{f}_p = \mathbf{f}_p d\alpha$. In this expression, we have $\mathbf{f}_p(\alpha) = f_{p\parallel} \hat{\mathbf{e}}_3 + f_{p\perp} \hat{\mathbf{e}}_\perp$, with α the angle labeling the flagella and $\hat{\mathbf{e}}_\perp = -\sin \alpha \hat{\mathbf{e}}_1 + \cos \alpha \hat{\mathbf{e}}_2$ the unit azimuthal vector along the *Gonium* periphery (Fig. 4a). Here, we choose $f_{p\parallel} > 0$ and $f_{p\perp} < 0$ to ensure a left-handed body rotation, with the ratio $f_{p\parallel}/f_{p\perp} =$

FIG. 3. Free swimming of *Gonium*. (a) Trajectories of many colonies under non-phototactic illumination, showing random swimming. Each colored line shows the path of one colony (sample size: 27 colonies). (b) Body rotation frequency ν_3 as a function of colony radius a (sample size: 159 colonies). (c) Mean velocity v_m normalised by the instantaneous swimming velocity v as a function of helix pitch angle χ (sample size: 430 colonies). The black line indicates relation $v_m/v = \cos \chi$ and green triangles along it are results from the numerical simulations as described in text.

$-\tan \beta$ which we assume independent of α , and β the tilt angle made by the peripheral flagella (Fig. 4b). The flagella therefore produce a net force and a net torque

$$\mathbf{F} = F_c \hat{\mathbf{e}}_3 + \int_0^{2\pi} \mathbf{f}_p d\alpha, \quad \mathbf{L} = \int_0^{2\pi} \mathbf{r} \times \mathbf{f}_p d\alpha. \quad (3)$$

In the absence of phototactic cues and for a perfectly symmetric *Gonium*, \mathbf{f}_p has no α dependence, and the force and torque are purely axial,

$$\mathbf{F}^{(0)} = \left[F_c + 2\pi f_{p\parallel}^{(0)} \right] \hat{\mathbf{e}}_3, \quad \mathbf{L}^{(0)} = 2\pi R f_{p\perp}^{(0)} \hat{\mathbf{e}}_3, \quad (4)$$

which satisfies $\mathbf{F}^{(0)} \cdot \mathbf{L}^{(0)} < 0$. For such a *straight swimmer*, the velocity \mathbf{U} and angular velocity $\mathbf{\Omega}$ resulting from the balance with the frictional forces and torques are also purely axial, along $\hat{\mathbf{e}}_3$ and $-\hat{\mathbf{e}}_3$, respectively.

The helical trajectories observed experimentally indicate that in most *Gonium* colonies the forces $\mathbf{f}_p(\alpha)$ produced by the peripheral flagella are not perfectly balanced. Such an unbalanced distribution produces nonzero components of \mathbf{F} and \mathbf{L} normal to $\hat{\mathbf{e}}_3$, which deflects the swimming direction of the colony. The simplest imbalance compatible with the observed helical trajectories is a modulation of the force developed by the peripheral flagella in the form

$$\mathbf{f}_p(\alpha) = \mathbf{f}_p^{(0)}(1 + \xi \cos \alpha), \quad (5)$$

with $0 \leq \xi \leq 1$ a parameter. With this choice, there is a stronger flagellar force along $\hat{\mathbf{e}}_1$ and the net force and torque acquire components in the plane ($\hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3$). Interestingly, the combined effect of these transverse force and torque components is to enable such unbalanced colonies to maintain their overall swimming direction.

To relate the uneven distribution of forces (5) to the helical pitch angle χ , we consider the geometry sketched in Fig. 1d: a *Gonium* colony swims along a helix whose axis is along $\hat{\mathbf{e}}_z$, with $\hat{\mathbf{e}}_3$ describing a cone around $\hat{\mathbf{e}}_z$ of constant apex angle ζ . The angular velocity vector $\mathbf{\Omega}$ is

therefore along $\hat{\mathbf{e}}_z$. In terms of Euler angles (Fig. 4a), this choice implies $\theta = \zeta$, $\psi = 0$ and $\mathbf{\Omega} = \dot{\phi}(\sin \zeta \hat{\mathbf{e}}_2 + \cos \zeta \hat{\mathbf{e}}_3)$ with constant $\dot{\phi} < 0$ (See Appendix C).

The helix pitch angle χ is the angle between \mathbf{U} and $\hat{\mathbf{e}}_z$. Because of the anisotropic resistance matrices and the axial force F_c produced by the central flagella, χ is larger than the angle ζ between $\hat{\mathbf{e}}_3$ and $\hat{\mathbf{e}}_z$: the colony exhibits large lateral excursions while maintaining its symmetry axis $\hat{\mathbf{e}}_3$ nearly aligned with the mean swimming direction $\hat{\mathbf{e}}_z$. Expanding to first order in the imbalance amplitude ξ , we find from force and torque balance

$$\tan \chi = \frac{\xi}{2} \left(\frac{l_3}{l_1} \tan \beta + \frac{k_3}{k_1} \frac{1}{\tan \beta} \frac{1}{1 + F_c/(2\pi f_{p\parallel}^{(0)})} \right), \quad (6)$$

so a symmetric *Gonium* ($\xi = 0$) swims straight ($\chi = 0$).

C. Comparison with experiments and computations

The continuous angular density of forces considered in the previous section is convenient to obtain a simple analytical description of the helical trajectories. However, to estimate the main hydrodynamic properties (flagella force and resistance matrices) from measurements, a more realistic description is needed that considers the drag exerted on the cell body by the flow induced by the flagellar forces. We assume for simplicity that all flagella produce equal individual forces F_i . With 4 central and 12 peripheral bi-flagellated cells, $F_c = 8F_i$ for the central cells, and $2\pi f_{p\parallel}^{(0)} = 24F_i \sin \beta$ and $2\pi f_{p\perp}^{(0)} = -24F_i \cos \beta$ for the axial and azimuthal force developed by the peripheral cells. We first restrict our attention to *straight* swimmers with balanced peripheral flagella force ($\xi = 0$).

To identify the physical parameters (flagella force F_i , flagella tilt angle β , effective radius R , translation and rotation friction coefficients k_1, k_3, l_1, l_3) from the experimental observations (swimming speed $v \simeq 40 \mu\text{m/s}$ and

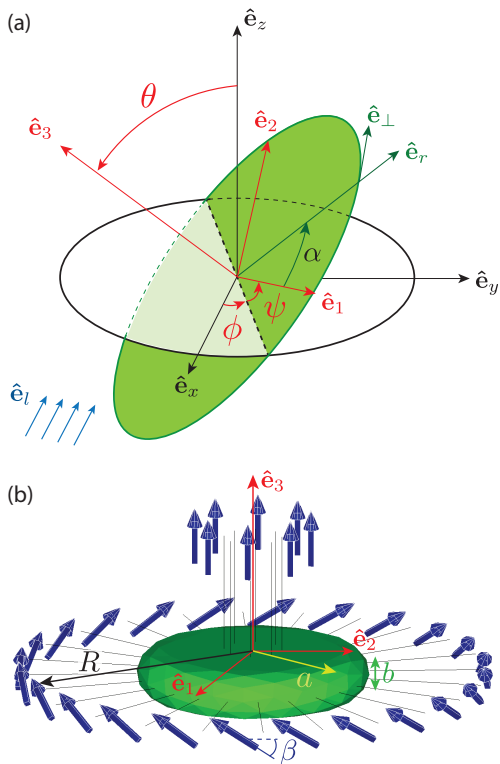

FIG. 4. Details of computational geometry. (a) Coordinates in the laboratory system and Euler angles. The frame $(\hat{e}_x, \hat{e}_y, \hat{e}_z)$ is attached to the laboratory; the frame $(\hat{e}_1, \hat{e}_2, \hat{e}_3)$ is attached to the *Gonium* body (green disk), with \hat{e}_3 the symmetry axis and (\hat{e}_1, \hat{e}_2) in the body plane. Euler angles (θ, ϕ, ψ) relate the two frames: by definition, θ is the angle between \hat{e}_z and \hat{e}_3 , ϕ is the angle from \hat{e}_x to the line of nodes (dotted line), and ψ is the angle from the line of nodes to \hat{e}_1 . In the *Gonium* body plane (\hat{e}_1, \hat{e}_2) , the flagella are labeled by the angle α , with $(\hat{e}_r, \hat{e}_\perp)$ the corresponding local frame such that $\cos \alpha = \hat{e}_1 \cdot \hat{e}_r$. For the computation of the phototactic response, we assume the light is incident along $\hat{e}_l = -\hat{e}_x$ (blue arrows). (b) *Gonium* geometry for simulations. The body (in green) is a thick disc with radius $a = 20 \mu\text{m}$ and thickness $b = 8 \mu\text{m}$. Flagella (length $20 \mu\text{m}$) associated with a point force $20 \mu\text{m}$ away from the cell body are attached to the body. The 8 central flagella generate thrust while the 24 peripheral ones are tilted by $\beta \simeq 30^\circ$, and generate both thrust and rotation.

body rotation frequency $\nu_3 \simeq 0.4 \text{ Hz}$), we combined computations and PIV measurements of the flow around a swimming *Gonium* colony. The computations, based on the boundary element method [34], are detailed in Appendix D. We use the simplified geometry of Fig. 4b: the cell body is a thick disk of radius a and thickness b , with 32 straight filaments representing the flagella pairs from the 16 cells, and a set of 32 point forces capturing the result of the flagella beating. These filaments also contribute to the hydrodynamic drag, and hence to the values of the friction coefficients k_1, k_3, l_1, l_3 . Flagella lengths are $30 - 40 \mu\text{m}$, but we consider in the computations the average of their shape over a beat cycle as contributing to the drag, which we expect to be in the

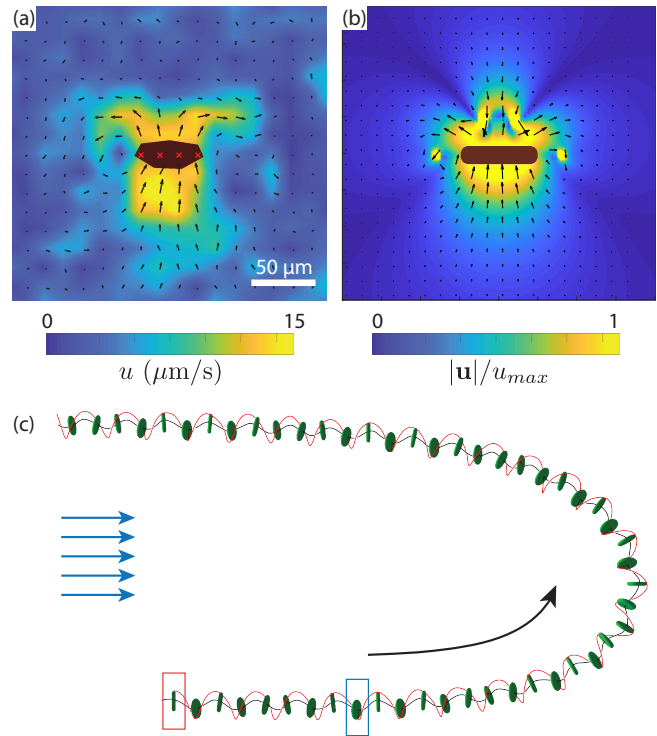

FIG. 5. Photoresponse of *Gonium*. (a-b) Flow fields around a colony swimming towards the top of the image, in the laboratory frame. (a) Micro-PIV measurements (the body is in black with red crosses). The background color shows the norm of the velocity, varying here up to $15 \mu\text{m/s}$. Scale bar is $50 \mu\text{m}$. (b) Numerical flow field using the point-force model. (c) Wavy trajectory of a colony, numerically computed for $\xi = 0.4$ and $\mu s_0 = 0.5$. The initial position is shown by the red rectangle, and the time when light is switched on from the left is indicated by the blue rectangle. Black line shows the trajectory, and the red line follows the position of the point of maximal force, $\alpha = 0$, highlighting rotation of the body.

range of $20 - 30 \mu\text{m}$. Comparing the velocity fields from PIV and numerics (Figs. 5a,b), we identify the location of the point force at about $20 \mu\text{m}$ from the cell body.

From this geometry, we compute the friction coefficients k_1, k_3, l_1, l_3 for several flagella lengths between 20 and $30 \mu\text{m}$, and tune the intensity of the point forces F_i and tilt angle β to obtain a good match to the experimental swimming and angular speeds. Tuning the flagella length to $20 \mu\text{m}$, so that $R \simeq 2a \simeq 40 \mu\text{m}$, appeared as the best match between experimental observations and numerical results. This corresponds to a point force per flagella $F_i \simeq 3.5 \text{ pN}$ and a tilt angle $\beta \simeq 30^\circ$. The friction coefficients are $k_1 \simeq 10$, $k_3 \simeq 13$, $l_1 \simeq 6$, and $l_3 \simeq 8$, as detailed in Appendix D. The flow field computed from these parameters (Fig. 5b) shows an overall structure in reasonable agreement with the PIV measurement performed around a freely swimming *Gonium* colony, which validates the methods. As expected, the far-field structure is typical of a *puller* swimmer, with inward flow in the swimming direction and outward flow normal to it.

FIG. 6. Phototactic reorientation of *Gonium*. (a) Reorientation trajectories of colonies under blue light stimulation shown alternately from right to left twice during 20 s. Each color line corresponds to a single colony and shows a swimming direction alternating to the right and left according to the change in light source position. (b) Instantaneous normalized velocity as a function of time for the blue trajectory in (a). Vertical lines indicate a change in the light source position: yellow shows times when the light is shone from the right, while green dashed lines stand for light coming from the left. (c) Reorientation time T_{180° as a function of the light intensity s_0 . The line shows $T_{180^\circ} \simeq 1/s_0$ for $s_0 < 1$ lux, consistent with Eq. (15), and a saturation at $T_{180^\circ} = 5$ s at larger s_0 . The grey shaded area corresponds to times longer than the video-camera trigger.

Note that the computed force is the flagellar thrust only which does not take into account the drag force, so that it overestimates the total force exerted by a flagellum on the fluid. An estimate for the true force is obtained by balancing the viscous force experienced by a colony $F_v = -k_3\eta Rv$ to the propulsive contributions of the flagella $8F_i + 24F_i \sin \beta \approx 20F_i$. The resulting force that a flagellum effectively applies on the fluid is of the order of 1 pN, a value close to the estimate for *Chlamydomonas* over a beating cycle [9].

We finally consider helical trajectories produced by unbalanced swimmers ($\xi \neq 0$), and include in the computation angular modulation of the peripheral flagella force (5). A typical trajectory is illustrated in Fig. 5c and Supplementary Movie 3 (note the non-phototactic part of the trajectory, between the red and blue rectangles). The black and red lines show the helical body trajectory and the position of the maximal force (unit vector \hat{e}_1). As expected, the anisotropic resistance matrices characteristic of the *Gonium* geometry produce a helical trajectory with large lateral excursion but moderate tilt of the body normal axis.

To relate the helical pitch angle χ to the imbalance parameter ξ (defined in Eq. (5)), we extract from the simulated trajectories the helix amplitude A , wavelength λ and mean velocity v_m , as described in the Appendix D and highlighted in Fig. 13. We deduce a pitch angle χ , observed to linearly increase with ξ , in close agreement with Eq. (6). The decrease in swimming efficiency with χ is also well reproduced, with numerical data closely following the geometrical prediction of $v_m/v = \cos \chi$, as evidenced by the black dots in Fig. 3c. From the experimental measurement $\chi \simeq 30^\circ \pm 13^\circ$, we deduce an average amplitude $\xi \approx 0.4$: the strongest flagella typically produce a force at least twice larger than the weakest ones. This surprisingly large value suggests that waviness is an important feature for the swimming of *Gonium*.

III. PHOTOTACTIC SWIMMING

A. Experimental observations

We now turn to the phototactic response of *Gonium*, which is triggered by adding to the previous experimental setup two blue LEDs on the sides of the chamber. The simplest configuration has the two lights arranged facing each other, as in Fig. 2a. Figure 6a displays the trajectories of a set of colonies reorienting as the two lights are alternately switched on and off for approximately 20s twice in a row, also seen in Supplementary Movie 4. These trajectories show various degrees of waviness, as in the non-phototactic experiments (Fig. 3a), however here their direction is no longer random but rather aligned with the incident light. At each change of light direction, a marked slowdown is also observed, as illustrated in Fig. 6b: just after the change in light, the swimming speed decreases by half for a few seconds, indicating a reduction in the flagella activity [25]. The variability in this drop can originate from out of plane swimming during reorientation, as we only have access to (x, y) projections of the trajectories.

A key feature to model the dynamics of the body reorientation towards light is the dependence of the flagella force on light intensity. We measured the time T_{180° to perform a turn-over as a function of the light intensity s_0 (Fig. 6c), restricting measurements to $s_0 < 100$ lux, so as to observe only *positive* phototaxis; at larger s_0 , an increasing fraction of colonies display *negative* phototaxis, swimming away from the light (the critical light intensity between positive/negative phototaxis varies with time during the diurnal cycle).

Figure 6c shows two phototactic regimes: A *linear* regime at moderate intensity ($s_0 < 1$ lux), for which $T_{180^\circ} \sim 1/s_0$, and a *saturated* regime at larger s_0 , for which $T_{180^\circ} \simeq 5 \pm 1$ s. In what follows we focus on the linear regime, in which the flagella activity is propor-

FIG. 7. Phototactic turn-over after a change of light incidence. *Gonium* colonies are initially swimming ($t < 0$ s) toward a light of constant intensity on the right. At $t = 0$ s, this light is switched off while another of controlled adjustable intensity s_0 is shone from the left. Trajectories are reported for $t > 0$ s, and have been shifted to the origin at $t = 0$ s. Colors along the lines show the time for $t > 0$ s.

tional to the light intensity. The constant reorientation time in the saturated regime may originate from a biological saturation in the signal transmission from the eye-spot to the flagella, or from a hydrodynamic limitation in the reorientation process itself: In this saturation regime, we have $\nu_3 T_{180^\circ} \simeq 2$, which is probably the fastest reorientation possible – during a 90° reorientation the *Gonium* colony performs one single rotation, *i.e.* each eye-spot detects the light variations only once.

A direct consequence of this dependence on light intensity is the shape of the trajectories during the reorientation process, illustrated in Fig. 7; here, only the reorienting part of the trajectories ($t > 0$ s) is displayed, and all are centered at (0,0) when the light is switched on from the left. At $s_0 = 0.4$ lux, colonies swim a long distance before facing the light, whereas they turn much more sharply at larger s_0 . The similar trajectories observed for $s_0 = 4$ lux and 40 lux are consistent with saturation in phototactic response for $s_0 > 1$ lux seen in Fig. 6c. Note that at $s_0 = 40$ lux, a small fraction of colonies (typically 10%) start to show erratic trajectories with a weak negative phototactic component.

A remarkable feature of Fig. 7 is that wavy trajectories gather near the center line, indicating a quick change in orientation, while smoother trajectories show a larger radius of curvature. This suggests that waviness, detrimental for swimming efficiency, is beneficial for phototactic efficiency: by providing a better scan of their environment, eye-spots from strongly unbalanced *Gonium* may better detect the light variations.

B. Reaction to a step-up in light

To explain the reorientation trajectories, we need a description of the flagella response to time-dependent variation in the light intensity. Measuring this response in freely swimming colonies is not possible because of their complex three-dimensional trajectories. To circumvent this difficulty, we use as in previous work [7, 13], a micropipette technique to maintain a steady view of the colony. Because of the linearity of the Stokes flow, the fluid velocity induced by the flagellar action is propor-

tional to the force they exert.

The experimental setup is described in Fig. 2b and Appendix A. Micropipettes of inner diameter slightly smaller than the *Gonium* body size (Fig. 8a) are used to catch colonies by gentle aspiration of fluid. An optical fiber connected to a blue LED is introduced in the chamber, and micro-PIV measurements are performed to quantify the changes in velocity field around the colony while varying the light intensity. Due to the presence of the micro-pipette, the measured velocities are not reliable on the pipette side (right-hand side of the images), but are accurate in the remainder of the field of view.

In these experiments we focus on phototactic stimulation in the form of a step-up in intensity (see also Supplementary Movie 5). The elementary flagella response to this is useful to compute the response to a more realistic change experienced by the flagella during the reorientation process. The micro-PIV experiments in Fig. 8b-d show the flow around a *Gonium* at three key moments of a step-up experiment: prior to light excitation, the flow is nearly homogeneous and circular, with peak velocities of $30 \mu\text{m/s}$ at a distance of $20 - 30 \mu\text{m}$ from the cell body. Immediately after light is shone from the bottom of the image (*i.e.* at 90° to the *Gonium* body plane), the flow symmetry is clearly broken: the velocity is strongly reduced in the illuminated part, down to $\simeq 15 \mu\text{m/s}$, about half the original value, while it remains essentially unchanged in the shadowed part. Finally, after a few seconds of constant illumination, the velocity gradually increases and the initial symmetry of the flow field is eventually recovered: the phototactic response is adaptive to the new light environment.

Flow velocities measured on the illuminated and shadowed sides are compared in Fig. 9a. Before light is switched on at $t = 0$, both curves follow similar variations around $30 \mu\text{m/s}$. At $t = 0$ s, the velocity on the illuminated side drops, while that on the opposite side remains nearly constant. After a few seconds, they tend to merge and variations are closer. As the flow velocity is proportional to the force in Stokes regime, this demonstrates a rapid drop followed by a slow recovery in the force from the illuminated side, while the force in the shadowed side remains essentially unaltered. We

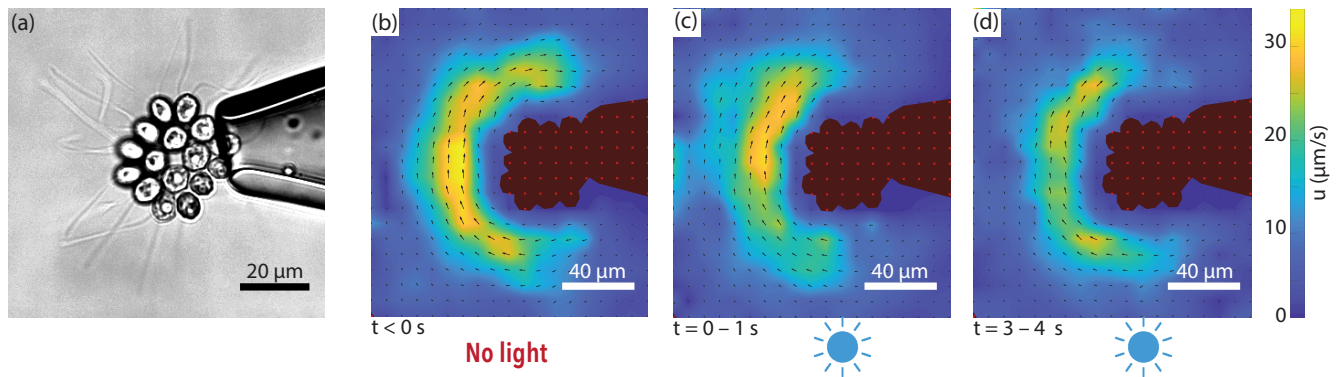

FIG. 8. Micropipette experiments. (a) A 16-cell colony held on a micro-pipette, viewed from posterior side. Flagella are clearly visible and their frequency can be followed as a function of time and light. The blue LED is located in the same plane as the micropipette, a few millimeters below the bottom of the image. (b) - (d) Velocity fields measured by micro-PIV, averaged over 1 s at three different times indicated below each panel. The *Gonium* is seen from the back (flagella away from us). Colormap is the same across the three images, from 0 – 30 $\mu\text{m/s}$. Light intensity $s_0 \approx 1$ lux.

note that these PIV measurements only provide information on the *azimuthal* component of the force $f_{p\perp}$, whereas the phototactic torque (3) is related to a non-axisymmetric distribution of the *axial* component of the force $f_{p\parallel}$. However, because of the small tilt angle of the flagella, $\beta \simeq 30^\circ$, changes in $f_{p\parallel}$ are too difficult to detect experimentally by PIV. We assume here that the angle β is not impacted by light, so that measurements of the azimuthal flow variations provide a good proxy for the axial flow variations.

The velocity induced by a flagellum (hence the applied force) is a complex combination of beat frequency and waveform [35]. These two quantities can be measured only in simple geometries, such as in *Chlamydomonas*, where the two flagella beat in the same plane. The complex three-dimensional flagellar organization in *Gonium* makes it difficult to quantify changes in waveform, but the response in beat frequency of each individual flagellum can be readily measured. A typical response to a step-up is displayed in Fig. 9b for the two flagella (*cis* and *trans*) of a single cell detecting the light. The typical drop-and-recovery pattern of the velocity response is also remarkably present in the beating frequency, showing that the force induced by the flagella is governed at least in part by the beat frequency. The initial frequency without light stimulation is about 15 Hz, with slightly lower values systematically found for the *cis*-flagellum (close to the eye-spot; see Fig. 1b). Both flagella show a reduced beating frequency when light is switched on, with a more pronounced drop for the *trans*-flagellum. In *Chlamydomonas*, the *cis*-flagellum shows a strong *decrease* [16, 31] while the *trans*-flagellum slightly *increases* its frequency, a behavior which we do not observe in *Gonium*. Although a *cis* - *trans* differentiation is the key to phototaxis in *Chlamydomonas*, this trait, not required for phototaxis at the level of the colony, is also present at the cell level in *Gonium*.

C. Adaptive model

Here we relate the drop-and-recovery response of the illuminated flagella to the phototactic reorientation. Whereas in earlier work on *Volvox* phototaxis [7] we considered the direct effect of changes in flagellar beating on the local fluid *velocity* on the surface, adopting a perspective very much like that in Lighthill's squirmer model [36], here we model the effect of light stimulation on the *force* developed by a peripheral flagella at an angle α as

$$\mathbf{f}_p(\alpha, t) = \mathbf{f}_p^{(0)}[1 - p_\alpha(t)], \quad (7)$$

with p_α the phototactic response. We neglect the possible phototactic response of the central flagella, which presumably do not contribute to the reorientation torque. We first describe the time-dependence of the response of a given flagellum α experiencing a step-up in light intensity, and then integrate the response from all flagella, taking into account eye-spot rotation, to deduce the reorientational torque, along the lines in recent work on *Chlamydomonas* [13].

The drop-and-recovery flagella response suggests using an adaptive model, which has found application in the description of sperm chemotaxis [37] and in phototaxis of both *Volvox* [7] and *Chlamydomonas* [13]: we assume that $p(t)$ follows the light stimulation on a rapid timescale τ_r , and is inhibited by an internal chemical process on a slower timescale τ_a described by a hidden variable $h(t)$. The phototactic response is assumed proportional to the light intensity, so we restrict ourselves to the linear regime at low s_0 . The two quantities h and p obey a set of coupled ODEs,

$$\tau_r \dot{p} = \mu s(t) - h - p \quad (8a)$$

$$\tau_a \dot{h} = \mu s(t) - h, \quad (8b)$$

where μ is a factor with units reciprocal to those of $s(t)$. This factor represents the biological processes which

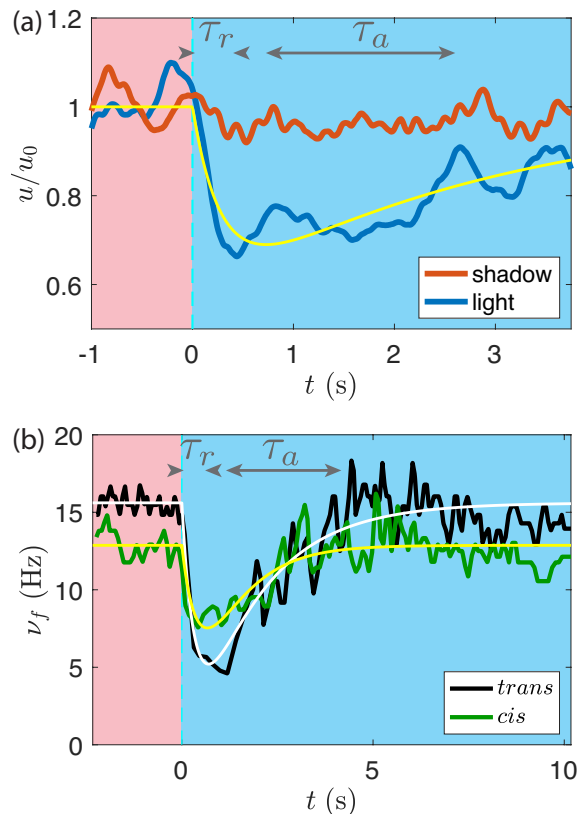

FIG. 9. Adaptive phototactic response. (a) Normalized azimuthal velocities in the shaded (red curve) and illuminated (blue curve) sides of a colony held on a micropipette (averages over two similar experiments). For $t < 0$ s there is only red illumination (no phototaxis). Blue light is switched on at $t = 0$ s. The yellow line displays the adaptive model, Eq. (7) and (9). (b) *Trans* and *cis* flagella beat frequencies ν_f (in black and green respectively), of a single cell receiving light (at $s_0 \approx 1$ lux) as a function of time. White and yellow lines are the respective best fits with Eqs. (7) and (9).

link the detection of light to the subsequent physical response. In the case of a step-up in light stimulation, $s(t) = s_0 H(t)$, with H the Heaviside function, we have

$$p_{step}(t) = \frac{\mu s_0}{1 - \rho} [e^{-t/\tau_a} - e^{-t/\tau_r}] H(t), \quad (9)$$

with $\rho = \tau_r/\tau_a$. This phototactic response (7)-(9), plotted as thin lines in Fig. 9 in the case $s_0 \approx 1$ lux, provides a reasonable description of the velocity and beating frequency, with $\tau_r \approx 0.4 \pm 0.1$ s and $\tau_a \approx 1.5 \pm 0.5$ s.

From this fit, we infer the value of the phototactic response factor: $\mu \approx 0.6 \pm 0.1$ lux $^{-1}$ and 0.8 ± 0.1 lux $^{-1}$ for the *cis* and *trans* flagella respectively. A somewhat lower value is obtained from the velocity signal, $\mu \approx 0.4 \pm 0.1$ lux $^{-1}$, which probably results from an average over the set of flagella on the illuminated side and a possible influence of a change in the flagella beating waveform. This disparity in the evaluation of μ underlines the complexity of the biological processes this variable summarizes. We retain in the following an average

FIG. 10. Experimental characteristic times (τ_r, τ_a) of the adaptive model. Data obtained from the flagella beat frequencies averaged for each colony (sample size: 34 colonies). Background color shows the gain function \mathcal{G} defined in Appendix F, Eq. (F8). Red line indicates the relation $\tau_r = \tau_a$.

value $\mu \approx 0.6 \pm 0.2$ lux $^{-1}$.

By linearity, the phototactic response to an arbitrary light stimulation $s(t)$ can be obtained as a convolution of the step-up response,

$$p(t) = \int_{-\infty}^t s(t') \frac{dp_{step}}{dt}(t-t') dt'. \quad (10)$$

During the reorientation process, the light $s(t)$ perceived by the peripheral cells varies on a time scale ω_3^{-1} . According to Eq. (10), the response to this light variation is band-pass filtered between τ_a and τ_r : an efficient response (*i.e.*, a short colony reorientation time) is naturally expected for $\tau_r \ll \omega_3^{-1} \ll \tau_a$. Biologically, the release of ions modifying the flagellar strength happens on a timescale τ_r much shorter than their dissipation in the organism, over a time τ_a . Mathematically, if both timescales are much shorter or much longer than the body rotation period $1/\omega_3$, then no phototactic reorientation can happen as the force asymmetry does not persist for a relevant time period. On the other hand, $\omega_3 \tau_r \approx \omega_3 \tau_a \approx 1$ can lead to negative phototaxis [13]. As shown in Appendix E, the maximum amplitude of the phototactic response is found in the limit $\tau_r/\tau_a \rightarrow 0$ in Eq. (9), yielding $p(t) = \mu s(t)$, which would correspond to a response following precisely the light stimulation. From our data, shown in Fig. 10, this behaviour has apparently not been selected by evolution, and we observe large fluctuations in the characteristic times τ_r and τ_a , suggesting other evolutionary advantages linked to this behaviour. Note that in *Chlamydomonas*, whose eye-spot is located at 45° from the *cis*-flagellum [38], an additional delay τ_d associated with body rotation is needed between the light detection by the eye-spot and activation of the flagellum.

To compute reorienting trajectories we consider for simplicity a perfectly balanced colony, with $\xi = 0$. In

terms of phototactic reorientation, this situation is somewhat singular: such a hypothetical colony would swim in straight line, so that a change of 180° in the light incidence, precisely opposed to their swimming direction, could not be detected by the peripheral eyespots. We therefore model a reorientation with a light incidence $\hat{\mathbf{e}}_l$ at 90° to the initial swimming direction; this is the optimal configuration for light detection. We consider in the following $\hat{\mathbf{e}}_l = -\hat{\mathbf{e}}_x$, and an initial orientation $\hat{\mathbf{e}}_3 = -\hat{\mathbf{e}}_y$, yielding $\theta = \pi/2$ and $\phi = 0$ (see Fig. 4). We assume for simplicity that θ remains constant during the reorientation: the colony axis $\hat{\mathbf{e}}_3$ rotates only in the plane $(\hat{\mathbf{e}}_x, \hat{\mathbf{e}}_y)$ and the phototactic torque is along $\hat{\mathbf{e}}_z$ only. At the end of the reorientation process, we have $\hat{\mathbf{e}}_3 = \hat{\mathbf{e}}_x$, as the *Gonium* is then facing the light, *i.e.* $\phi = \pi/2$.

The light perceived by a cell is

$$s(\kappa) = s_0 \kappa H(\kappa), \quad (11)$$

with $\kappa = -\hat{\mathbf{e}}_l \cdot \hat{\mathbf{e}}_r$ the projected light incidence along the local normal unit vector $\hat{\mathbf{e}}_r$,

$$\kappa = \cos \phi \cos(\alpha + \psi) - \cos \theta \sin \phi \sin(\alpha + \psi). \quad (12)$$

From Eq. (10), at a given time t , each flagellum labeled by the angle α has a phototactic response $p_\alpha(t)$ resulting from the light $s(t')$ perceived at all times $t' < t$. This light intensity depends on its orientation, as described by Eq. (11)-(12): it originates both from the (fast) body spin $\dot{\psi} = \omega_3$ and the (slow) reorientation angular velocity $\dot{\phi}$. For simplicity, the computation of p_α (given in Appendix F) assumes $\dot{\psi} \gg \dot{\phi}$, which is a valid approximation in the linear regime ($s_0 < 1$ lux). Using the force (7), the reorientational torque is

$$L_z = R f_{p\parallel}^{(0)} \int_{-\pi/2}^{\pi/2} p_\alpha \cos \alpha d\alpha. \quad (13)$$

Balancing this torque with the vertical component of the frictional torque, $L_{vz} = -\eta R^3 l_1 \dot{\phi}$, leads to the o.d.e

$$\dot{\phi} = \frac{1}{\tau} \cos \phi \quad (14)$$

with a relaxation time expressed as a product of three factors,

$$\tau = \frac{1}{\mu s_0} \frac{1}{\mathcal{G}} \frac{2l_1 \eta R^2}{\pi f_{p\parallel}^{(0)}}. \quad (15)$$

Here, $\tau \sim 1/\mu s_0$ is a dependence consistent with the linear response assumption, and we have introduced a gain function $\mathcal{G}(\omega_3 \tau_r, \omega_3 \tau_a) \in [0, 1]$ associated with the adaptive response, which is function of the non-dimensional relaxation times $\omega_3 \tau_a$ and $\omega_3 \tau_r$, and described in Appendix F. This gain function is such that $\mathcal{G} \rightarrow 1$ in the optimal case $\omega_3 \tau_r \rightarrow 0$ and $\omega_3 \tau_a \rightarrow \infty$ (no adaptive filtering), yielding the fastest reorientation time. With the pN scale of forces, the $\sim 20 - 30 \mu\text{m}$ scale of R and the

viscosity of water, we naturally find a timescale on the order of seconds, as in experiment.

Equation (14) is analogous to the problem of a door pulled by a constant force with viscous friction. Its solution with initial condition $\phi(0) = 0$ is

$$\phi(t) = \pi/2 - 2 \tan^{-1}(e^{-t/\tau}), \quad (16)$$

which asymptotes to $\phi(\infty) = \pi/2$: we have obtained the expected phototactic reorientation, on a timescale τ . In the case of a full reorientation (180°), this solution applies only for the second half of the reorientation, for $\phi(t)$ increasing from 0 to $\pi/2$ (the first half is simply deduced by symmetrizing Eq. (16) for $t < 0$). Note that the slope at 0 is simply $1/\tau$, which offers a quick way to estimate this characteristic time.

D. Comparison to the experiments

To study how far *Gonium* colonies are from the optimum gain $\mathcal{G} = 1$, we plot in Fig. 10 the adaptive timescales (τ_r, τ_a) measured for a set of colonies under illumination intensity $s_0 \approx 1$ lux. These data were obtained by averaging the response times of the beating frequency of each flagellum. The measurements are centered around $(\tau_r, \tau_a) \approx (0.1, 2)$ s, corresponding to values of \mathcal{G} between 0.5 and 0.7, which is in the upper half, but somewhat far from the optimum expected for an ideal swimmer. The error bars highlight the variability in the response times among flagella within a colony, and this evidences how biological variations divert *Gonium* from its physical optimum.

Until now, we have ignored the helical nature of the trajectories in the phototactic reorientation process. Including waviness in the adaptive model of Sec. III C would be a considerable analytical task, because the light variation perceived by each eyespot would depend on the three Euler angles and their time derivatives. Instead, we performed a series of direct numerical studies of phototactic reorientation using the computational model previously introduced, combining in the flagella force the azimuthal modulation (5) and the phototactic response (7). Typical trajectories, obtained for various imbalance parameter ξ (and hence pitch angle χ), are illustrated in Fig. 11a and Supplementary Movie 3, for a light intensity corresponding to $\mu s_0 = 0.5$. The trajectories clearly show a faster reorientation for wavier colonies, consistent with the experimental observations in Fig. 7. The trajectories show about 10 body rotations during the reorientation (*i.e.*, $\dot{\phi}/\dot{\psi} \simeq 0.05$), indicating that the linear regime assumption used in the model is satisfied for this value of μs_0 .

The reorientation dynamics of such wavy swimmers is illustrated in Fig. 11b, showing the angle $\sin^{-1}(-\hat{\mathbf{e}}_3 \cdot \hat{\mathbf{e}}_l)$ as a function of time. For a straight swimmer, this angle is simply $\phi(t)$: it increases monotonically from $-\pi/2$ to $\pi/2$ following Eq. (16) symmetrized in time. For an unbalanced swimmer, the symmetry axis $\hat{\mathbf{e}}_3$ describes a

FIG. 11. Numerical results for the phototactic response. (a) The reorientation trajectories of three wavy swimmers are shown for $\mu s_0 = 0.5$ (corresponding to $s_0 \approx 0.3$ lux). They are initially swimming away from the light source, and then turn around after the light is switched on from the left when colonies are at the origin (yellow star). (b) Evolution of ϕ as a function of time for the same swimmers. Light is turned on at $t = 0$. The thin black dashed, dash-dotted and dotted lines are the respective fits using Eq. (16), with $\tau = 4.5 \pm 0.1$ s, $\tau = 4.0 \pm 0.1$ s and $\tau = 3.9 \pm 0.1$ s. Curves are also adjusted with an amplitude parameter to account for the noise in the swimming direction, respectively 0.99, 0.93 and 0.83 for $\xi = 0.05$, 0.2 and 0.5.

cone of apex angle ζ (as described in Sec. II) around the mean swimming direction: $\sin^{-1}(-\hat{\mathbf{e}}_3 \cdot \hat{\mathbf{e}}_l)$ therefore increases from $-\pi/2 + \zeta$ to $\pi/2 - \zeta$. The angle obtained from numerical simulations indeed shows oscillations superimposed on a mean evolution that is still remarkably described by the straight-swimmer law [Eq. (16), in dotted lines], with the asymptotic values $\pm\pi/2$ simply replaced by $\pm(\pi/2 - \zeta)$. Increasing the imbalance parameter ξ clearly increases the amplitude of the oscillations when the light is switched on, yielding a better scan of the environment and hence a shorter reorientation time but does not affect the characteristic timescale τ . Combined with the reduced mean velocity $v_m = v/\cos\chi$ (Fig. 3c), this faster reorientation finally produces the sharper trajectories observed in Fig. 11a. Our simulations therefore successfully capture the main features of the phototactic reorientation dynamics observed in *Gonium* colonies.

Finally, we also take advantage of the helical trajectory-

FIG. 12. Reorientation time T_{180° , normalised by τ , as a function of the pitch angle χ . Data (white discs) are extracted from 133 trajectories, under all light conditions presented in Fig. 6c. The white dashed line shows Eq. (17) and the color background indicates the number of experimental measurements within a bin (size $8^\circ \times 2$).

ries to evaluate the reorientation time T_{180° , as measured in Fig. 6c. It can be simply defined as twice the time for $\phi(t)$ to increase from 0 to $\pi/2$. According to Eq. (16), this time is infinite for a perfectly straight swimmer ($\chi = 0$), unless a tolerance in the final alignment is considered. For a wavy swimmer ($\chi > 0$), however, the reorientation time is finite, and it can be simply estimated by considering the pitch angle χ as the tolerance for final alignment. Assuming that the straight-swimmer model (16) still applies, the approximate final alignment condition $\phi(T_{180^\circ}/2) \simeq \pi/2 - \chi$ yields

$$T_{180^\circ}(\chi) = -2\tau \ln[\tan(\chi/2)], \quad (17)$$

which diverges in the straight-swimmer limit $\chi \rightarrow 0$. Data presented in Fig. 12 show the turn-over time normalised by τ , obtained by fitting Eq. (16) to the trajectories, as a function of the pitch angle χ of these helical trajectories. The color background highlights the density of measurements, peaked close to the white line which displays Eq. (17). If data are scattered due to the inherent biological noise of swimmers, our model appears to stress the lower boundary of the distribution of points: for a given χ , reorientation cannot happen faster than defined by Eq. (17). Data are again gathered around $\chi \approx 30^\circ$, which appears as an optimum: at smaller values of χ , the reorientation time T_{180° diverges, while for larger χ , the effective swimming speed is strongly lowered, as seen in Fig. 3c, leading to a slower reorientation.

IV. CONCLUSIONS

We have presented a detailed study of motility and phototaxis of *Gonium pectorale*, an organism of intermediate complexity within the *Volvocine* green algae. In its flagellar dynamics it combines beating patterns found

in *Chlamydomonas* and *Volvox*, and has a distinct symmetry compared to the approximate bilateral symmetry of the former and the axisymmetry of the latter. Our experimental observations are consistent with a theory based on adaptive response exhibited solely by the peripheral cells, on a time scale comparable to the rotation period of the colony around the axis normal to the body plane. The precise biochemical pathways that underlie this adaptive response remain unclear. As with other green algae [7, 13], the response and adaptation dynamics serve to define a kind of bandpass filter of response centered around the colony rotation period, extending from tenths of a second to several seconds. It is natural to imagine that evolution has chosen these scales to filter out environmental fluctuations that are both very rapid (such as might occur from undulations of the water’s surface above a colony) and very slow (say, due to passing clouds), to yield distraction-free phototaxis. Finally, we have observed that colonies with helical trajectories that arise from slightly imbalanced flagellar forces are shown to have enhanced reorientation dynamics relative to perfectly symmetric colonies. Taken together, these experimental and theoretical observations lend support to a growing body of evidence [39] suggesting that helical swimming by tactic organisms is not only common in Nature, but possesses intrinsic biological advantages.

ACKNOWLEDGMENTS

We thank Kyriacos Leptos for initial experimental assistance and inspiration for the model, Lucie Domino for preliminary studies of *Gonium*, and David Page-Croft, Caroline Kemp, and John Milton for vital technical support. We are also grateful to Matt Herron and Shota Yamashita for insights into *Gonium* structure. This work was supported in part by Wellcome Trust Investigator Award 207510/Z/17/Z (REG & HM), Institut Universitaire de France (FM), the Japan Society for the Promotion of Science (KAKENHI Grant Nos. 17H00853 & 17KK0080 to TI), Established Career Fellowship EP/M017982/1 from the Engineering and Physical Sciences Research Council and Grant No. 7523 from the Gordon and Betty Moore Foundation (REG).

Appendix A: Materials and methods

Data underlying the figures in this paper are available in the Supplemental Material [40].

Culture conditions

Wild-type *Gonium pectorale* colonies (strain CCAC 3275 B from the Cologne Biocenter) were grown in standard *Volvox* medium in an incubator (Binder) at 24°, under 3800 lux illumination in a 14:10h light-dark cycle.

Observation of swimming

Chambers were prepared using two glass slides, sealed with Frame-Seal Incubation Chambers (SLF0201, 9x9 mm, BIO-RAD Laboratories). They were subsequently mounted on a Nikon TE2000-U inverted microscope for observation with a 4× or 10× Nikon Plan Fluor objective. Non-phototactic red illumination of the samples was achieved with a long pass filter (620 nm) in the light path. Observations were recorded with a high-speed video camera (Phantom V311; see also below) at 30 fps. A pair of blue LEDs (M470L2, Thorlabs), connected to LED drivers (LEDD1B, Thorlabs), were placed on either sides of the chamber, and separately controlled, as described in Fig. 2a. To assure maximum photoresponse, the wavelength of 470 nm was chosen to be close to the absorption maximum rhodopsin [41], the protein in the eyespot responsible for light detection [14].

Micropipette experiments

We used borosilicate glass pipettes (Sutter Instruments, outer diameter 1.0 mm, inner diameter 0.75 mm), a pipette puller (P-97, Sutter Instruments) and a multi-function microforge controller (DMF1000, World Precision Instruments) to produce micropipettes of inner diameter $\sim 20 \mu\text{m}$, with polished edges.

Chambers were fabricated by gluing short spacers to glass slides with UV-setting glue (NOA61), with UV exposure for 1 min (ELC-500 lamp, Electro-Lit Corporation), leaving apertures at 90° for the micropipette and the optical fiber to enter the chamber, as sketched in Fig. 2b. Colonies were caught on the micropipette, through which fluid was gently aspirated via a 10 ml syringe (BD Luer-Lok 305959). The optical fiber (FT400EMT, Thorlabs) was connected to a 470 nm LED (M470F3, Thorlabs) and driver (DC2200, Thorlabs), enabling intensity and timing control. We took care that the fiber end enters the liquid in the chamber to avoid losses of light by reflection at the air-water interface, and that it is aligned with the tip of the micropipette. Synchronization of the light source to the camera was made via a NI-DAQ (BNC-2110, National Instruments). Light intensities were measured with a lux meter (Lutron LX-101). We verified proportionality between the intensity (in lux) from of the optical fiber and the current (mA) provided by the driver, to extrapolate light intensities below 1 lux, where the meter saturates.

Microparticle image velocimetry (PIV) experiments are conducted by adding non-fluorescent beads (Polybead Polystyrene Cat. 07310, Polysciences), of diameter 1 μm , to the *Gonium* suspension. Image acquisition was performed on a similar microscope with a 20× Plan Fluor (Nikon) or a 63× water immersion Plan Achromat objective (Zeiss) with a 45–60 Nikon adapter, connected to the same video-camera recording at 200 fps. Image analysis was performed via the Matlab tool PIVlab, with a

window size adapted to the chosen microscope objective to ensure the presence of at least 3 – 5 particles.

Appendix B: Inferring Helical Motion from Planar Projections

We define three velocities for a helical trajectory: the mean velocity $v_m = \lambda/T$, where T is the time to cover one wavelength λ , the true (3D) instantaneous velocity v_{3D} and the apparent (2D) instantaneous velocity $v_{2D} = v$. From microscopy, we access v_m and v , from which we deduce v_{3D} . To relate these velocities, we rewrite the helical trajectory in parametric form:

$$(x(z), y(z)) = A(\cos kz, \sin kz). \quad (\text{B1})$$

where $k = 2\pi/\lambda$. The instantaneous velocity is $v_{3D} = l/T$, where $l = \int_0^\lambda ds$ is the curved length covered by *Gonium*. In 3D, we have $ds = dz\sqrt{1+x_z^2+y_z^2}$, yielding

$$\begin{aligned} v_{3D} &= \frac{1}{T} \int_0^\lambda \sqrt{1+(kA)^2} dz \\ &= \frac{\lambda}{T} \sqrt{1+\tan^2 \chi} = \frac{v_m}{\cos \chi}. \end{aligned} \quad (\text{B2})$$

If we assume that the 2D plane of view is (x, z) , then for the apparent (2D) instantaneous velocity v we now have $ds = dz\sqrt{1+x_z^2}$, so

$$v_{2D} = \frac{1}{T} \int_0^\lambda \sqrt{1+\tan^2 \chi \sin^2(kz)} dz, \quad (\text{B3})$$

which is an elliptic integral of the second kind of parameter $\tan^2 \chi$. For small χ , a Taylor expansion gives $v_m/v_{3D} \simeq 1 - \chi^2/2$ and $v_m/v_{2D} \simeq 1 - \chi^2/4$. For the typical values found for *Gonium*, $\chi \approx 30^\circ$, we deduce that $v_{2D}/v_{3D} \simeq 0.93$, and therefore conclude that approximating the instantaneous velocity by its 2D projection is reasonable.

Appendix C: Helical trajectories

We relate here the pitch angle χ of the helical trajectories to the uneven distribution of flagellar forces. The geometry is shown in Fig. 1d, with $\hat{\mathbf{e}}_3$ the symmetry axis of the *Gonium* body. In this geometry, the rotation vector $\boldsymbol{\Omega}$ is along the mean swimming direction $\hat{\mathbf{e}}_z$. The pitch angle χ is the angle between the instantaneous velocity \mathbf{U} and $\hat{\mathbf{e}}_z$. The symmetry axis of the *Gonium* body describes a cone around z of constant apex angle ζ , with $\zeta < \chi$ because of the anisotropic resistance matrices. The Euler angles for this geometry are $\theta = \zeta$, $\dot{\phi} = \omega_3/\cos \zeta$ and $\dot{\psi} = 0$. The frictional torque (1b) is thus

$$\mathbf{L}_v = -\eta R^3 \begin{bmatrix} l_1 \dot{\phi} \sin \zeta \sin \psi \\ l_1 \dot{\phi} \sin \zeta \cos \psi \\ l_3 (\dot{\psi} + \dot{\phi} \cos \zeta) \end{bmatrix}. \quad (\text{C1})$$

The simplest defect compatible with such a helical trajectory is a modulation of the axial force developed by the peripheral flagella in the form (c.f. Eq. (5))

$$\mathbf{f}_p(\alpha) = \mathbf{f}_p^{(0)}(1 + \xi \cos \alpha), \quad (\text{C2})$$

with ξ a ‘‘defect’’ parameter. We assume here that β does not depend on α , so that the defect affects the peripheral and axial components $f_{p\parallel}$ and $f_{p\perp}$ in the same way. From this force distribution, the total force and torque (3) are

$$\mathbf{F} = [F_c + 2\pi f_{p\parallel}^{(0)}] \hat{\mathbf{e}}_3 + \pi \xi f_{p\perp}^{(0)} \hat{\mathbf{e}}_2, \quad (\text{C3})$$

$$\mathbf{L} = 2\pi R f_{p\perp}^{(0)} \hat{\mathbf{e}}_3 - \pi \xi R f_{p\parallel}^{(0)} \hat{\mathbf{e}}_2. \quad (\text{C4})$$

Since the force and the torque now have components along $\hat{\mathbf{e}}_2$, the velocity and angular velocity do as well. The phase choice in Eq. (5) assigns maximum flagella force along $\hat{\mathbf{e}}_1$, and implies $L_1 = 0$, so $\psi = 0$ in Eq. (C1).

To compute the angle ζ , we first solve for the torque-angular velocity relation along $\hat{\mathbf{e}}_2$ and $\hat{\mathbf{e}}_3$,

$$-\eta R^3 l_1 \dot{\phi} \sin \zeta = -\pi \xi R f_{p\parallel}^{(0)}, \quad (\text{C5})$$

$$-\eta R^3 l_3 \dot{\phi} \cos \zeta = 2\pi R f_{p\perp}^{(0)}. \quad (\text{C6})$$

Solving for ζ yields

$$\tan \zeta = \xi \frac{l_3}{2l_1} \tan \beta \quad (\text{C7})$$

with $\tan \beta = -f_{p\parallel}^{(0)}/f_{p\perp}^{(0)}$. A symmetric *Gonium* ($\xi = 0$) naturally has $\zeta = 0$.

The helix pitch angle χ , the angle between the instantaneous velocity \mathbf{U} and the mean swimming direction $\hat{\mathbf{e}}_z$, is found by solving the velocity-force relation along $\hat{\mathbf{e}}_2$ and $\hat{\mathbf{e}}_3$,

$$\eta R k_1 U_2 = \pi \xi f_{p\perp}^{(0)}, \quad (\text{C8})$$

$$\eta R k_3 U_3 = F_c + 2\pi f_{p\parallel}^{(0)}. \quad (\text{C9})$$

The angle ζ' between $\hat{\mathbf{e}}_3$ and \mathbf{U} is

$$\tan \zeta' = \frac{U_2}{U_3} = \xi \frac{k_3}{2k_1} \frac{1}{\tan \beta} \frac{1}{1 + F_c/(2\pi f_{p\parallel}^{(0)})}. \quad (\text{C10})$$

We note that the vectors $\boldsymbol{\Omega}$ ($\parallel \hat{\mathbf{e}}_z$), $\hat{\mathbf{e}}_3$ and \mathbf{U} are in the same plane ($\hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3$). The total angle χ between $\hat{\mathbf{e}}_z$ and \mathbf{U} is therefore simply $\chi = \zeta + \zeta'$. For small ξ , we have $\tan \chi \simeq \tan \zeta + \tan \zeta'$, yielding Eq. (6),

$$\tan \chi \simeq \frac{\xi}{2} \left(\frac{l_3}{l_1} \tan \beta + \frac{k_3}{k_1} \frac{1}{\tan \beta} \frac{1}{1 + F_c/(2\pi f_{p\parallel}^{(0)})} \right). \quad (\text{C11})$$

We can rewrite this relation using the discret point-force model. Assuming that all the individual flagellar

FIG. 13. Properties of wavy helical trajectories. (a) Amplitude A of the oscillations and wavelength λ of the helix as a function of the defect parameter ξ . (b) Pitch angle χ and swimming efficiency v_m/v as a function of the defect parameter ξ . The dashed line shows the theoretical prediction for χ as a function of ξ , obtained from Eq. (6).

forces F_i are identical, we have $F_c = 8F_i$ and $2\pi f_{pl}^{(0)} = 24F_i \sin \beta$, yielding

$$\tan \chi \simeq \frac{\xi}{2} \left(\frac{l_3}{l_1} \tan \beta + \frac{k_3}{k_1} \frac{1}{\tan \beta + 1/(3 \cos \beta)} \right). \quad (\text{C12})$$

The helix parameters A and λ are derived by expressing the velocity in the laboratory frame,

$$U_x(t) = -(U_2 \cos \zeta - U_3 \sin \zeta) \sin(\dot{\phi}t), \quad (\text{C13a})$$

$$U_y(t) = (U_2 \cos \zeta - U_3 \sin \zeta) \cos(\dot{\phi}t), \quad (\text{C13b})$$

$$U_z = U_2 \sin \zeta + U_3 \cos \zeta. \quad (\text{C13c})$$

with $\dot{\phi} = \omega_3 / \cos \zeta$. Here, U_z corresponds to v_m , the mean velocity along z . Integrating these equations in time yields the helix amplitude and wavelength,

$$A = \frac{U_3 \sin \zeta - U_2 \cos \zeta}{\dot{\phi}}, \quad (\text{C14a})$$

$$\lambda = 2\pi \frac{U_2 \sin \zeta + U_3 \cos \zeta}{\dot{\phi}}. \quad (\text{C14b})$$

Using $\tan \chi = 2\pi A / \lambda$, we obtain

$$\tan \chi = \frac{U_3 \tan \zeta - U_2}{U_3 + U_2 \tan \zeta}, \quad (\text{C15})$$

which can be shown to be equivalent to Eq. (C12) to first order in ξ .

Appendix D: Numerical methods

Here we give details of the numerical techniques and show characteristic values extracted from the computed

wavy trajectories. We use the geometry shown in Fig. 4b and described in the text. Typical Reynolds numbers for swimming *Gonium* are $\sim 10^{-3}$, in Stokes regime. The velocity of the surrounding fluid at a position \mathbf{x} can therefore be expressed as boundary integrals,

$$\begin{aligned} \mathbf{u}(\mathbf{x}) = & -\frac{1}{8\pi\mu} \int_{\text{body}}^{\text{cell}} \mathbf{J}(\mathbf{x}, \mathbf{x}') \cdot \mathbf{q}(\mathbf{x}') dA(\mathbf{x}') \\ & -\frac{1}{8\pi\mu} \sum_{j=1}^{32} \int_{\text{flagella}} [\mathbf{J}(\mathbf{x}, \mathbf{x}') + \mathbf{W}(\mathbf{x}, \mathbf{x}')] \cdot \mathbf{f}(\mathbf{x}') dl_j(\mathbf{x}') \\ & -\frac{1}{8\pi\mu} \sum_{j=1}^{32} \mathbf{J}(\mathbf{x}, \mathbf{x}') \cdot \mathbf{F}_j(\mathbf{x}'). \end{aligned} \quad (\text{D1})$$

Here, \mathbf{J} is the Stokeslet kernel, \mathbf{W} the kernel for slender body theory, \mathbf{q} the traction force on the cell body, \mathbf{f} the traction force on flagella, and \mathbf{F} the point force generated by the flagella. The first term of the r.h.s of Eq. (D1) represents the drag of the cell body, which is solved by a boundary element method with a mesh of 320 triangles. The second term accounts for the drag of the 32 flagella, which is solved by slender body theory with 10 slender elements per flagellum. The third term represents thrust and spin forces generated by flagella. A no-slip velocity boundary condition is applied on the cell body and along the flagella; force- and torque-free conditions are applied to the whole body. Detailed functional forms and the velocity along the flagella can be found in Itoh *et al.* [34]; here we solve Eq. (D1) in a similar manner.

The amplitude A of the oscillations of the computed wavy trajectories, using the force variation around *Gonium* given by Eq. (5), linearly increases with the strength ξ of the imbalance (Fig. 13), while the wavelength λ is hardly impacted. The deduced pitch angle χ therefore also linearly increases with ξ , in good agreement with Eq. (6), plotted by the dashed line. This enables us to deduce the experimental imbalance amplitude, as $\chi \simeq 30^\circ$ corresponds to $\xi \simeq 0.4$. Finally, the decrease in swimming efficiency v_m/v follows the geometrical prediction $v_m/v = \cos \chi$, as plotted in Fig. 3c.

Appendix E: Maximum of the adaptive response

Defining $x = t/\tau_r$ in the step response (9) for $t > 0$ we have

$$p_{\text{step}}(x) = \frac{\mu s_0}{1 - \rho} (e^{-\rho x} - e^{-x}), \quad (\text{E1})$$

where again $\rho = \tau_r / \tau_a$. The maximum response obtained by setting $dp_{\text{step}}/dx = 0$ occurs at $x^* = -(1 - \rho)^{-1} \ln \rho$, with the magnitude $p_{\text{step}}^* = p_{\text{step}}(x^*)$ given by the amusing function

$$p_{\text{step}}^* = \rho^{\rho/(1-\rho)}. \quad (\text{E2})$$

As shown in Fig. 14, this has a maximum at $\rho = 0$, confirming the statement in Sec. III C that the maximum amplitude response is found in the limit $\tau_r / \tau_a \rightarrow 0$.

FIG. 14. Maximum amplitude (E2) of the adaptive phototactic response to a step-up in light intensity, as a function of the ratio $\rho = \tau_r/\tau_a$. Red circle indicates experimental average.

Appendix F: Phototactic gain function

We estimate here the photoresponse p_α at an arbitrary angle α around *Gonium*. This allows computation of the phototactic torque (3) from the flagella force (7). The balance with the viscous torque eventually leads to the phototactic reorientation trajectory. This implies the definition of a gain function \mathcal{G} . From (10), the response to light stimulation $s(t)$ is

$$p(t) = \frac{\mu}{1-\rho} \int_{-\infty}^t s(t') \left[\frac{e^{-(t-t')/\tau_r}}{\tau_r} - \frac{e^{-(t-t')/\tau_a}}{\tau_a} \right] dt'. \quad (\text{F1})$$

In this model, $p(t)$ has a slight negative overshoot when $s(t)$ decreases. However, for $\tau_r \ll \tau_a$, one has $p(t) > 0$ for almost all time, and the integration of p among the flagella on the illuminated side remains positive.

To evaluate the integral, we use the following geometry. We consider that only flagella on the illuminated side of the *Gonium*, defined by $\alpha = -\pi/2 \dots \pi/2$, contribute to the reorientation torque. A flagellum at angle α has traveled from $-\pi/2$ to α at constant spin ω_3 . After its transit to the dark side, each flagellum loses the memory of its previous transit on the illuminated side, so that $p =$

0 when it reaches $\alpha = -\pi/2$. With $s(\alpha) = s_0 \cos \phi \cos \alpha$ and using $\alpha = \omega_3 t$, Eq. (F1) becomes

$$p_\alpha = \frac{\mu s_0 \cos \phi}{1-\rho} [I(\omega_3 \tau_r, \alpha) - I(\omega_3 \tau_a, \alpha)]. \quad (\text{F2})$$

with

$$\begin{aligned} I(A, \alpha) &= \frac{1}{A} \int_{-\pi/2}^{\alpha} \cos \alpha' e^{-(\alpha-\alpha')/A} d\alpha' \quad (\text{F3}) \\ &= \frac{1}{A^2 + 1} \left[(A \sin \alpha + \cos \alpha) \right. \\ &\quad \left. + A e^{-(\alpha+\pi/2)/A} \right]. \quad (\text{F4}) \end{aligned}$$

We finally compute the torque (3) from the flagella force (7). Because of the delay induced by the adaptive response, the torque is no longer along \hat{e}_z , implying a change in θ . Since we assumed $\theta = \pi/2$ earlier, we consistently neglect this effect, and consider only the z component of the torque,

$$L_z = R f_{p\parallel}^{(0)} \int_{-\pi/2}^{\pi/2} p_\alpha \cos \alpha d\alpha. \quad (\text{F5})$$

Inserting (F2), we rewrite this integral as

$$L_z = R f_{p\parallel}^{(0)} \frac{\mu s_0 \cos \phi}{1-\rho} [J(\omega_3 \tau_r) - J(\omega_3 \tau_a)], \quad (\text{F6})$$

where

$$\begin{aligned} J(A) &= \int_{-\pi/2}^{\pi/2} I(A, \alpha) \cos \alpha d\alpha \\ &= \frac{1}{A^2 + 1} \left(\frac{\pi}{2} + \frac{A^3}{A^2 + 1} (1 + e^{-\pi/A}) \right). \quad (\text{F7}) \end{aligned}$$

We have $J(0) = \pi/2$ and $J(A) \simeq 2/A$ for $A \gg 1$. Balancing this torque with the z component of the friction torque $L_{vz} = -\eta R^3 l_1 \dot{\phi}$ yields a differential equation in the form (14), from which we identify the gain function

$$\mathcal{G}(\omega_3 \tau_r, \omega_3 \tau_a) = \frac{2 [J(\omega_3 \tau_r) - J(\omega_3 \tau_a)]}{\pi (1-\rho)}. \quad (\text{F8})$$
